

Diane M. Debinski, Jennet C. Caruthers, Dianne Cook, Jason Crowley, and Hadley Wickham. 2013. Gradient-based habitat affinities predict species vulnerability to drought. *Ecology*

Appendix C: Single species model summary

In the following document, there are visual and numerical summaries of the model used to fit butterfly species count data by year. The species included in this document are limited to the ones that had an aggregate count of ten or higher over all years, regions and meadow types. Of the 87 total species, 60 met this criterion and are included in this document. Note that the models fit on the following pages are fit to the individual species, which is different than the mixed model fit to all the data.

To model this data, Poisson regression (a form of a Generalized linear model) was utilized, as it is natural to assume that the response variable (count) follows the Poisson distribution. The model used can be summarized as such:

$$\begin{aligned} \log_e(Y_{ijk}) = & \beta_0 + \beta_1(YEAR) + \alpha_i(REGION) + \gamma_j(MTYPE) + \alpha\gamma_{ij}(REGION * MTYPE) \\ & + \alpha\beta_{i1}(REGION * YEAR) + \gamma\beta_{j1}(MTYPE * YEAR) + \epsilon_{ijk} \end{aligned}$$

$i \in \{1, 2\}$, representing $REGION \in \{\text{Gallatin, Teton}\}$
 $j \in \{1, \dots, 6\}$, representing $MTYPE \in \{\text{M1, M2, M3, M4, M5, M6}\}$

(C1)

In the model, year, region, and meadow type are the three explanatory variables. The year runs from 1997 to 2007, with some exceptions that are noted in the paper. There are two regions that butterflies were collected from in this study, the Gallatins and the Tetons, the latter of which is the baseline for the fitted models shown in this document. The third main effect included in this model is meadow type, which runs from M1 (hydric) to M6 (xeric). The M1 level is the baseline in the fitted model.

The model includes an interaction between region and meadow type, which allows the intercept of the regression line over year to differ between meadow types within a particular region (and vice versa). The model also includes an interaction between year/region and year/meadow type, which allows the slope of the regression line to differ among different regions and meadow types, respectively. For an example of a species where the slope of the regression over year clearly depends on region/meadow type, see *Speyeria mormonia*.

Once the model was fit to each species separately, it was determined which species' abundances showed the most significant trend over year, or between regions or meadow types. This was accomplished by considering two models for each species: the model shown above, and the model without any terms associated with year. A full vs. reduced F-test was then run to determine the difference in variation explained between the two models, and the p-value based on this test calculated. **The species are shown in order of significance, with the species showing most significant**

trend, *Cercyonis oetus*, shown first. The fitted model for each combination of region and meadow type is included, as well as estimated coefficients for the fitted model and some model diagnostics. Also included for each species is a plot of abundance over time, by region and meadow type, with the fitted model plotted over the data (in red).
